We describe the construction of a high performance parallel computer composed of PC components, as well as the performance test in lattice QCD.

1. INTRODUCTION

The ZhongShan University Computational Physics group's interests [1] cover such topics as lattice QCD[2–5] quantum instanton[6] and quantum chaos[7]. Most of these topics can be studied through Monte Carlo simulation, but can be quite costly in terms of computing power. In order to do large scale numerical investigations of these topics, we required a corresponding development of our local computing resources.

The demarcation between super computers and personal computers has been further blurred in recent years by the high speed and low price of modern CPUs and networking technology and the availability of low cost or free software. By combining these three elements - all readily available to the consumer - one can assemble a true super computer that is within the budget of small research labs and businesses.

We document the construction and performance of a Beowulf cluster of PCs, configured to be capable of parallel processing.

2. SYSTEM

Our cluster consists of ten PC type computers[8], each with two Pentium III-500 CPUs inside. The logic behind dual CPU machines is that one can double the number of processors without the expense of additional, cases, power supplies, motherboards, network cards, et cetera. Also, the inter-node communication speed is faster for each pair of processors in the same box as com-

pared to communication between separate computers. Each computer has an 8GB EIDE hard drive, 128 MB of memory, a 100Mbit/s Ethernet card, a simple graphics card a floppy drive and a CDROM. In practice the CDROM, the floppy drive, and even the graphics card could be considered extraneous, as all interactions with the nodes could be done through the network. One computer has a larger hard disk (20 GB), and a SCSI card for interaction with a tape drive. For the entire cluster we have only one console consisting of a keyboard, mouse and monitor.

A fast Ethernet switch handles the inter-node communication. The switch has 24 ports so there is ample room for future expansion of the cluster to up to a total of 48 processors. Of course it is possible to link multiple switches or use nodes with more than two processors, so the possibilities for a larger cluster are nearly limitless.

We have installed a Red Hat Linux 6.1 distribution. It automatically supports dual CPU computers. It is also able to support a Network File System (NFS), allowing all of the nodes in the cluster to share hard disks, and a Network Information System (NIS), which standardizes the usernames and passwords across the cluster.

We can use the cluster for parallel processing by using the message passing interface (MPI), a library of communication functions and programs that allow for communication between processes on different CPUs. The programmer must design the parallel algorithm so that it appropriately divides the task among the individual

Machine	μ -sec/link	MB/sec
SX-4	4.50	45
SR2201	31.4	28
Cenju-3	57.42	8.1
Paragon	149	9.0
ZSU Cluster	3.98	11.5

Performance of MPI QCD benchmark [9].

processors. He or she must then include message passing functions in the code which allow information to be sent and received by the various processors.

3. PERFORMANCE

As we primarily developed the cluster for numerical simulations of lattice QCD, we have also performed a benchmark which specifically tests the performance in a parallel lattice QCD code. The algorithm can conveniently divide the lattice and assign the sections to different processors.

Hioki and Nakamura [9] provide comparison performance data on SX-4 (NEC), SR2201 (Hitachi), Cenju-3 (NEC) and Paragon (Intel) machines. Specifically, we compare the computing time per link update in microseconds per link and the inter-node communication speed in MB/sec. The link update is a fundamental computational task within the QCD simulation and is therefore a useful standard. The test was a simulation of improved pure gauge action (1×1 plaquette and 1×2 rectangle terms) on a 16^4 lattice. In each case the simulation was run on 16 processors. The results are summarized in Table 1.

A widely used QCD program is the MILC code [10]. It has timing routines provided so that one can use the parallelized conjugate gradient routine in the simulation as a benchmark. Furthermore, as this code is very versatile and is designed to be run on a wide variety of computers and architectures. This enables quantitative comparison of our cluster to both other clusters and commercial supercomputers. In the MILC

benchmark test we ran to a convergence tolerance of 10^{-5} per site. For consistency with benchmarks performed by others, we simulated Kogut-Susskind fermions.

We have run the benchmark test for different size lattices and different numbers of processors. It is useful to look at how performance is affected by the number of CPUs, when the amount of data per CPU is held fixed, that is each CPU is responsible for a section of the lattice that has L^4 sites. For one CPU, the size of the total lattice is L^4 . For two CPUs it is $L^3 \times 2L$. For four CPUs the total lattice is $L^2 \times (2L)^2$; for eight CPUs, $L \times (2L)^3$, and for 16 CPUs the total size of the lattice is $(2L)^4$.

Note that the falloff in performance with increased number of CPUs is dramatic. This is because inter-processor message passing is the slowest portion of this or any MPI program and from two to sixteen CPUs, the amount of communication per processor increases by a factor of four. Table 2 shows that for a lattice divided into 2^j hypercubes, each of size L^4 , there will be j directions in which the CPUs must pass data to their neighbors. The amount of communication each processor must perform is proportional to the amount of interface per processor. As this increases, per node performance decreases until $j = 4$ and every lattice dimension has been divided (for a $d = 4$ simulation). and the per-processor performance should remain constant as more processors are added. The shape of this decay is qualitatively consistent with $1/j$ falloff.

Of course there are other ways to divide a four-dimensional lattice. The goal of a particular simulation will dictate the geometry of the lattice and the therefore the most efficient way to divide it up (generally minimizing communication). A four-CPU simulation using a $4L \times L^3$ lattice has the four hypercubic lattice sections lined up in a row (as opposed to in a 2×2 square for a $L^2 \times (2L)^2$ lattice) and has the same amount of communication per CPU as does the $L^3 \times 2L$ two-CPU simulation. In a benchmark test the per-CPU performance was comparable to the performance in the two-CPU test.

For a single processor, there is a general decrease in performance as L increases, as shown in

I.D.	H.	L.V.	T.I.	I./CPU
j	2^j	$L^{4-j} \times (2L)^j$	$2^j j L^3$	$j L^3$
0	1	L^4	0	0
1	2	$L^3 \times 2L$	$2L^3$	L^3
2	4	$L^2 \times (2L)^2$	$8L^3$	$2L^3$
3	8	$L \times (2L)^3$	$24L^3$	$3L^3$
4	16	$(2L)^4$	$64L^3$	$4L^3$

Table 2

Boundary sizes for division of a lattice into 1,2,4,8 and 16 hypercubes of size L^4 . Here I.D. stands for interface directions, H. for hypercubes (CPUs) L.V. for lattice volume, T.I. for total interface, and I./CPU for interface/CPU respectively.

L	single processor speed (Mflops)
4	161.5
6	103.2
8	78.6
10	76.4
12	73.9
14	75.9

Table 3

Single CPU performance of MILC code.

Table 3. This is well explained in [11] as due to the larger matrix size using more space outside of the cache memory, causing slower access time to the data.

For multiple CPUs there is in performance improvement as L is increased[8]. The explanation for this is that the communication bandwidth is not constant with respect to message size. For very small message sizes, the bandwidth is very poor. It is only with messages of around 10kB or greater that the bandwidth reaches the full potential of the fast Ethernet hardware, nearly 100Mbit/sec. With a larger L , the size of the messages is also, improving the communication efficiency. The inter-node communication latency for our system is $102\mu s$. As inter-node communi-

cation is the slowest part a parallel program this far outways the effect of cache misses.

To summarize, a parallel cluster of PC type computers is an economical way to build a powerful computing resource for academic purposes. On an MPI QCD benchmark simulation it compares favorably with other MPI platforms. The price/performance ratio[8] is $\$7/Mflop$. It is drastically cheaper than commercial supercomputers for the same amount of processing speed. It is particularly suitable for developing research groups in countries where funding for pure research is more scarce. We have been doing large scale calculations of hadron and glueball spectrum[12].
